Abstract The immediate evolutionary space accessible to HIV is largely determined by how single amino-acid mutations affect fitness. These mutational effects can shift as the virus evolves. However, the prevalence of such shifts in mutational effects remains unclear. Here we quantify the effects on viral growth of all amino-acid mutations to two HIV envelope (Env) proteins that differ at >100 residues. Most mutations similarly affect both Envs, but the amino-acid preferences of a minority of sites have clearly shifted. These shifted sites usually prefer a specific amino acid in one Env, but tolerate many amino acids in the other. Surprisingly, shifts are only slightly enriched at sites that have substituted between the Envs – and many occur at residues that do not even contact substitutions. Therefore, long-range epistasis can unpredictably shift Env's mutational tolerance during HIV evolution, although the amino-acid preferences of most sites are conserved between moderately diverged viral strains.

Introduction

HIV's envelope (Env) protein evolves very rapidly. The major group of HIV-1 that is responsible for the current pandemic originated from a virus that entered the human population ~100 years ago (????). The descendants of this virus have evolved so rapidly that their Envs now have as little as 65% protein identity (?). For comparison, protein orthologs shared between humans and mice have only diverged to a median identity of 78% over 90 million years (??).

Env's rapid evolution has dire consequences for anti-HIV immunity, since it erodes the efficacy of most neutralizing antibodies (????). Because of this public-health importance, numerous studies have experimentally characterized aspects of the "evolutionary landscape" that Env traverses. The immediate evolutionary space accessible to any given Env is largely defined by the effects on viral fitness of all single amino-acid mutations to Env. Most mutational studies have measured how just a small number of these mutations affect viral growth in cell culture, although it has recently become possible to use deep mutational scanning to measure the effects of many (??) or even all (?) single amino-acid mutations to an Env variant.

But interpreting these studies in the context of Env evolution requires addressing a fundamental question: How informative are mutational studies of a single protein variant about constraints on long-term evolution? During protein evolution, substitutions at one site can change the effect of

mutations at other sites (?????). We will follow the nomenclature of ? to refer to these changes in mutational effects as *shifts* in a site's amino-acid preferences. Such shifts can accumulate as substitutions become entrenched via epistatic interactions with subsequent changes (????) – although the magnitude of these shifts is usually limited (????).

Given that the Envs of circulating HIV strains represent a vast collection of homologs that often differ at >100 residues, shifts in amino-acid preferences could make the outcome of any study highly dependent on the Env used. Indeed, epistasis among a few combinations of Env mutations has been experimentally demonstrated (?), and epistatic fitness landscapes have been computationally inferred for a variety of HIV proteins (????) including Env (?). However, the only protein-wide experimental studies of how amino-acid preferences shift during evolution have examined proteins that are structurally far simpler than Env, which forms a large heavily glycosylated heterotrimeric complex that transitions through multiple conformational states (??).

Here we use an improved version of a previously described deep mutational scanning strategy (?) to measure the effects on viral growth of all single amino-acid mutations to two transmitted-founder virus Envs that differ by >100 mutations. We compare these complete maps of mutational effects to identify sites that have shifted in their amino-acid preferences between the Envs. Most sites show no detectable shifts, but 30 sites have clearly shifted preferences. These shifted sites usually prefer a specific amino acid in one Env but have shifted to tolerate many amino acids in the other Env. The shifted sites cluster in structure, but are often distant from any amino-acid substitutions that distinguish the two Envs, demonstrating the action of long-range epistasis. By aggregating our measurements for both Envs, we identify sites that evolve faster or slower in nature than expected given the functional constraints measured in the lab, probably due to pressure for immune evasion. Overall, our work provides complete across-strain maps of mutational effects that inform analyses of Env's evolution and function.

Results

Two Envs from clade A transmitted-founder viruses

The viruses most relevant to HIV's long-term evolution are those which are transmitted from human-to-human. However, the only prior work that has measured how all Env amino-acid mutations affect HIV growth is a study by some of us (?) that used a late-stage lab-passaged CXCR4-tropic virus (LAI; ?). The properties of Env can vary substantially between such late-stage viruses and the transmitted-founder viruses relevant to HIV's long-term evolution (????).

We therefore selected Envs from two transmitted-founder viruses, BG505.W6M.C2.T332N and BF520.W14M.C2 (hereafter referred to as BG505 and BF520), that were isolated from HIV-infected infants shortly after mother-to-child transmission (???). The BG505 Env has been extensively studied from a structural standpoint (??????), and variants of this Env are being tested as a vaccine immunogens (???). We used the T332N variant of BG505 Env because it has a common glycosylation site that is targeted by many anti-HIV antibodies (?). The BF520 Env was isolated from an infant who developed an early broad anti-HIV antibody response (??). We have previously created comprehensive codon-mutant libraries of the BF520 Env and used them to map HIV antibody escape (?), but these BF520 libraries have not been characterized with respect to how mutations affect viral growth.

Both BG505 and BF520 are from clade A of the major (M) group of HIV-1. **Figure 1** shows the phylogenetic relationship among these two Envs and other clade A sequences. BG505 and BF520 are identical at 721 of the 836 pairwise-alignable protein sites (86.2% identity). However, in our experiments we mutagenized only the ectodomain and transmembrane domain of Env, and excluded the signal peptide and cytoplasmic tail. The reason is that we measure how Env mutations affect viral growth, which is influenced both by the functionality of Env protein molecules and their expression level. Mutations in the signal peptide and cytoplasmic tail commonly affect Env expression level (???), so we excluded these regions with the goal of reducing the degree to which we

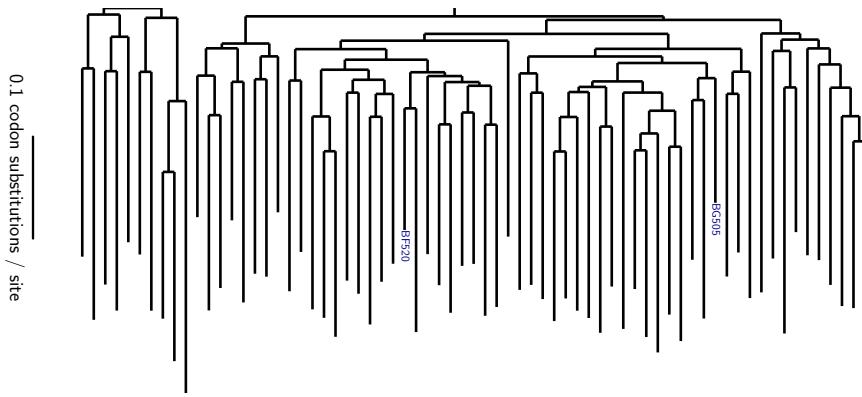

Figure 1. Phylogenetic tree showing the relationship of BG505 and BF520 to other clade A Envs. The tree shows the 69 Envs in the alignment in *Figure 1*-source data 1, which is a subsample of clade A sequences from the group M alignment in the Los Alamos HIV sequence database (<http://www.hiv.lanl.gov>). Sites not mutagenized in our experiments (the signal peptide and cytoplasmic tail) or that are poorly alignable were masked as indicated in *Figure 1*-source data 2, leaving 616 alignable sites. The pairwise identity of BG505 and BF520 to other sequences at alignable sites is in *Figure 1*-*Figure Supplement 1*. The tree topology was inferred using RAxML (?) under the GTRCAT model of nucleotide substitution, and branch lengths were optimized under the M0 Goldman-Yang model (?) using phydms (?).

Figure 1-Figure supplement 1. Pairwise identity of all Env sequences to BG505 and BF520.

Figure 1-source data 1. The alignment of clade A *env* coding sequences is in *cladeA_alignment.fasta*.

Figure 1-source data 2. The 240 Env sites masked in all phylogenetic analyses because they were not mutagenized in our experiments or are poorly alignable are listed in *alignment_mask.csv*.

simply identified mutations that affected Env expression. In the ectodomain and transmembrane domains of Env, BG505 and BF520 are identical at 549 of the 616 sites (89.1% identity) that are alignable across clade A Envs (*Figure 1*-source data 1, *Figure 1*-source data 2). The divergence between BG505 and BF520 therefore offers ample opportunity to investigate mutational shifts during Env evolution.

Deep mutational scanning of each Env

We have previously described a deep mutational scanning strategy for measuring how all amino-acid mutations to Env affect HIV growth in cell culture, and applied this strategy to the late-stage lab-adapted LAI strain (?). Here we made several modifications to this earlier strategy to apply it to transmitted-founder Envs and to reduce the experimental noise. This last consideration is especially important when comparing Envs, since it is only possible to reliably detect differences that exceed the magnitude of the experimental noise. Our modified deep mutational scanning strategy is in *Figure 2A*. This approach had the following substantive changes: instead of SupT1 cells, we used SupT1.CCR5 cells (SupT1 cells lentivirally transduced to express CCR5 in addition to CXCR4 (?)) to support growth of viruses with transmitted-founder, CCR5-tropic Envs; we used more virions for the first passage ($\geq 3 \times 10^6$ versus 5×10^5 infectious units per library) to avoid bottlenecking library diversity; and rather than performing a full second passage we just did a short high-MOI infection to enable recovery of *env* genes from infectious virions without bottlenecking (*Figure 2A*). We performed this deep mutational scanning in full biological triplicate for both BG505 and BF520 (*Figure 2B*). Our libraries encompassed all codon mutations to all sites in Env except for the signal peptide and cytoplasmic tail.

The deep mutational scanning effectively selected for functional Envs as evidenced by strong purifying selection against stop codons. *Figure 3A* shows the average frequency of mutations across Env in the plasmid mutant libraries, the mutant viruses, and wildtype controls as determined from the deep sequencing. The mutant viruses show clear selection against stop codons and many nonsynonymous mutations (*Figure 3A*). This selection is more apparent if we correct for

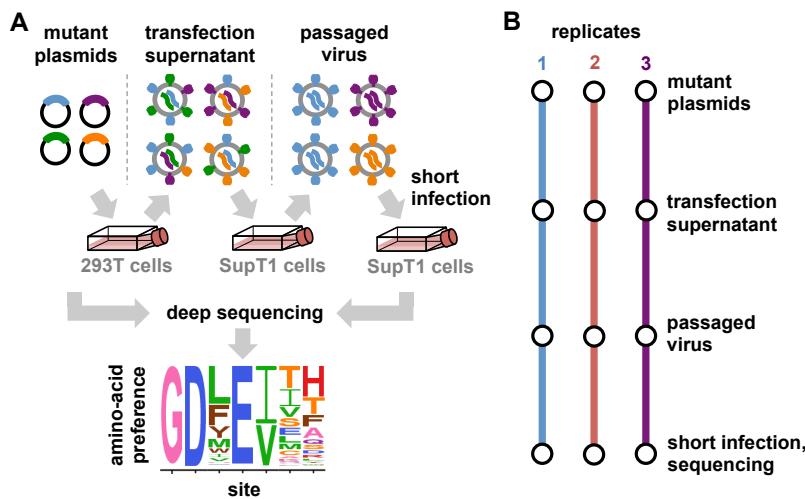

Figure 2. Deep mutational scanning workflow. **(A)** We made libraries of proviral HIV plasmids with random codon-level mutations in the *env* gene. The number of mutations per gene approximately followed a Poisson distribution with a mean between 1 and 1.5 (*Figure 2–??*). We transfected the plasmids into 293T cells to generate mutant viruses, which lack a genotype-phenotype link since cells are multiply transfected. To establish a genotype-phenotype link and select for Env variants that support HIV growth, we passaged the libraries in SupT1.CCR5 cells for four days at a low multiplicity of infection (MOI) of 0.01. To isolate the *env* genes from only viruses that encoded a functional Env protein, we infected the passaged libraries into SupT1.CCR5 cells at high MOI and harvested reverse-transcribed non-integrated viral DNA after 12 hours. We then deep sequenced the *env* genes from these final samples as well as the initial plasmid library, using molecular barcoding to reduce sequencing errors. We also deep sequenced identically handled wildtype controls to estimate error rates. Using these sequencing data, we estimated the preference for each of the 20 amino acids at each site in Env. These data are represented in logo plots, with the height of each letter proportional to that site's preference for that amino acid. **(B)** We conducted this experiment in full biological triplicate for both BG505 and BF520, beginning each replicate with independent creation of the plasmid mutant library. These replicates therefore account for all sources of noise and error in the experiments.

Figure 2–Figure supplement 1. Sanger sequencing of selected clones from the mutant plasmid libraries.

the background error rates estimated from the wildtype controls (*Figure 3–Figure Supplement 1*). The error-corrected frequencies of stop codons drop to 3%–16% of their original values (*Figure 3–Figure Supplement 1*), with the residual stop codons probably due to some non-functional virions surviving due to complementation by other co-infecting virions. The error-corrected frequencies of nonsynonymous mutations also drop substantially (43%–49% of their original values), whereas the frequencies of synonymous mutations drop only slightly (85%–95% of their original values). These trends are consistent with the fact that nonsynonymous mutations are often deleterious, whereas synonymous mutations often (although certainly not always, see *?*) have only mild effects on viral growth. *Figure 3A* only summarizes one aspect of the deep mutational scanning data, but Supplementary files 1 and 2 contain detailed plots showing all aspects of the data (read depth, per-site mutation rate, etc) as generated by the *dms_tools2* software (*?*, https://jbloomlab.github.io/dms_tools2/).

We used the deep mutational scanning data to estimate the preference of each site in Env for each amino acid via the analysis method described in *?*. As graphically illustrated in *Figure 2A*, the preferences for each site are normalized to sum to one. Our libraries were mutagenized at 670 sites in BG505 and 662 sites in BF520, so $670 \times 20 = 13,400$ and $662 \times 20 = 13,240$ preferences were estimated for each Env, respectively. The correlations between the preferences from different experimental replicates are in *Figure 3B*. These replicate-to-replicate correlations are substantially higher than those for the deep mutational scanning of LAI Env by *?*, which had replicate-to-replicate Pearson correlations of only $R = 0.45$ to 0.50 .

While the replicates are well correlated across all replicates for both BG505 and BF520, the

Figure 3. The deep mutational scanning selects for functional Envs and yields measurements that are well correlated among replicates. **(A)** The average per-codon mutation frequency when sequencing plasmids encoding wildtype Env (*DNA*), plasmid mutant libraries (*mutDNA*), mutant viruses after the final infection (*mutvirus*), and virus generated from wildtype plasmids (*virus*). Mutations are categorized as nonsynonymous, synonymous, or stop codon. The *DNA* samples show that sequencing errors are rare, and the *virus* samples show that viral-replication errors are well below the frequency of mutations in the *mutDNA* samples. Comparing the *mutvirus* to *mutDNA* shows clear purifying selection against stop codons and some nonsynonymous mutations, particularly after subtracting the background error rates given by the *virus* and *DNA* samples (*Figure 3–Figure Supplement 1*). More extensive plots from the analysis of the deep sequencing data are in Supplementary files 1 and 2. **(B)** Correlations between replicates in the measured preferences of each site in Env for all 20 amino acids. Blue indicates replicate measurements on BF520, red indicates replicate measurements on BG505, and gray indicates across-Env measurements of BF520 versus BG505. R is the Pearson correlation coefficient. The numerical values for the preferences are in *Figure 3–source data 1*. *Figure 3–Figure Supplement 2* shows the correlations using contour rather than scatter plots.

Figure 3–Figure supplement 1. Numerical frequencies of mutations.

Figure 3–Figure supplement 2. Correlations plotted on a contour rather than a scatter plot.

Figure 3–source data 1. Preferences for each replicate and averages are in `all_prefs_unscaled.zip`.

replicates for BG505 are more correlated with each other than with replicates for BF520, and vice versa (*Figure 3B*, compare red and blue versus gray plots). This fact hints that there are some shifts in amino-acid preferences between the two Envs – something that is investigated with more statistical rigor later in this paper. Note also that there is a trend for highly preferred amino acids to be more strongly preferred in BG505 than BF520 (most high-preference points in the gray plots in *Figure 3B* fall above the diagonal); however, this trend does not necessarily reflect differences between the Envs. Rather, there were modest differences in the stringency of selection between our deep mutational scans of BG505 and BF520 (*Figure 3–Figure Supplement 1* shows that purifying selection better purged stop codons in BG505). In the next section, we correct for these experimental differences by calibrating each dataset to match the stringency of selection in nature.

Model	ΔAIC	LogLikelihood	nParams	stringency	$\bar{\omega}$	ω_α	ω_β	nsites $\omega_r > 1$	nsites $\omega_r < 1$
ExpCM BF520	0.0	-35218.8	7	2.8	1.4	1.0	0.7	66	35
ExpCM BG505	269.0	-35353.3	7	2.1	1.3	0.9	0.7	65	53
Goldman-Yang M5	3455.1	-36941.4	12	nan	0.8	0.6	0.7	14	211

Table 1. Evolutionary models informed by the deep mutational scanning describe HIV's evolution in nature much better than a standard substitution model. Shown are the results of maximum likelihood fitting of substitution models to the clade A phylogeny in [Figure 1](#). Experimentally informed codon models (ExpCM, ?) utilizing the across-replicate average of the deep mutational scanning describe Env's natural evolution far better than a standard codon substitution model (the M5 model of ?) as judged by comparing the Akaike information criteria (ΔAIC , ?). Both ExpCM models have a stringency parameter >1 . All models draw ω from a gamma distribution, and the table shows the mean ($\bar{\omega}$) and shape parameters (ω_α and ω_β) of this distribution. The last two columns show the number of sites evolving faster ($\omega_r > 1$) or slower ($\omega_r < 1$) than expected at a false discovery rate of 0.05, as determined using the approach in ? (see also the last section of the Results). Analyses were performed using phydms (<http://jbloomlab.github.io/phydms/>). **Table 1-source data 1** shows the results for additional substitution models.

Table 1-source data 1. Results for phylogenetic models where ω is not drawn from a gamma-distribution or where the preferences are averaged across sites to eliminate the site specificity are in `modelcomparison.md`.

Amino-acid preferences of the Envs and their relationship to HIV evolution

The most immediate question is how authentically the experimental measurements describe the actual selection on Env function in nature. Direct comparisons between experimentally measured amino-acid preferences and amino-acid frequencies in natural sequences are confounded by the fact that the natural sequences are evolutionarily related. This problem can be overcome by making the comparison in a phylogenetic context to account for the evolutionary relationships among sequences.

Specifically, we used our deep mutational scanning data to construct experimentally informed codon models (ExpCM's) for Env's evolution. An ExpCM is a phylogenetic substitution model that incorporates the functional constraints measured in a deep mutational scanning experiment (?). If the experiment captures much of the actual evolutionary constraint on a gene, then an ExpCM will describe the gene's natural evolution better than a standard phylogenetic codon substitution model. The reason is that standard codon substitution models (such as the commonly used Goldman-Yang style models; ?) only model functional constraint via a single parameter that represents the rate of fixation of nonsynonymous protein-altering mutations relative to synonymous ones; this parameter is called dN/dS or ω . In contrast, an ExpCM accounts for the preference of each site for each of the 20 amino acids under the functional selection in the deep mutational scan, and then additionally adds an ω parameter that represents the relative rate of nonsynonymous to synonymous substitutions after accounting for these functional constraints (??). Importantly, since we expect some sites in Env to be under diversifying selection from immunity, we extended the ExpCM's described in ? to draw ω from a gamma distribution as is commonly done for codon-substitution models (?).

Table 1 shows that ExpCM's informed by the deep mutational scanning of either BG505 or BF520 describe the natural evolution of Env vastly better than a standard codon substitution model. In addition to the improved fit of the ExpCM's, we can also interpret the ω parameter. Recall that for standard codon substitution models, ω is simply the rate of fixation of nonsynonymous mutations relative to synonymous ones. For such models, the gene-wide average ω is almost always <1 , since purifying selection purges many functionally deleterious amino-acid mutations even for adaptively evolving proteins (?). Indeed, **Table 1** shows that Env's gene-wide average ω is <1 for a standard model. But for ExpCM's, ω is the relative rate of nonsynonymous to synonymous substitutions *after* accounting for functional constraints measured in the deep mutational scanning (?). But for ExpCM's, the gene-wide average ω is >1 (**Table 1**), indicating that external selection (e.g., from immunity) drives Env to fix amino-acid mutations faster than expected under a null model that only accounts for functional constraints on the protein.

ExpCM's also have a stringency parameter that relates selection in the experiments to that in

nature. Essentially, this experiment indicates how strongly natural selection prefers the amino acids that are preferred in the deep mutational scanning (?). A stringency parameter >1 indicates that natural selection prefers the same amino acids as the experiments, but with greater stringency. Both ExpCM's have stringency parameters >1 (**Table 1**) – a finding that makes sense, since the stop-codon analysis in the previous section suggests that the experimental selections are more lax than natural selection on HIV.

For the entire rest of the paper, we use the experimentally measured preferences re-scaled by the stringency parameters in **Table 1**. The reason we do this is to distinguish genuine differences between the two Envs from mere variation in the strength of selection between the two sets of experiments. Re-scaling both sets of preferences to optimally describe Env evolution in nature is a principled way to standardize the measurements; see ? and the Methods section entitled “Re-scaling the preferences” for a more detailed explanation.

A qualitative way to assess if the deep mutational scanning authentically describes selection on Env function is to visually compare the measurements with existing knowledge. **Figure 4** and **Figure 5** show the re-scaled across-replicate average of the amino-acid preferences for each Env. At sites of known functional importance, these preferences are usually consistent with prior knowledge. For instance, residues T257, D368, E370, W427, and D457 are important for Env binding to CD4 (?), and all these amino acids are highly preferred in our deep mutational scanning (**Figure 4** and **Figure 5**). Likewise, Env has 10 disulfide bonds (linking sites 54-74, 119-205, 126-196, 131-157, 218-247, 228-239, 296-331, 378-445, 385-418, and 598-604), most of which are important for function (?) – and the cysteines at these sites are highly preferred in our deep mutational scanning. The deep mutational scanning is also consistent with prior knowledge about sites that are tolerant of mutations. For instance, Env has five variable loops that mostly evolve under weak constraint in nature (??) – and most sites in these loops are mutationally tolerant in our deep mutational scanning (see sites indicated by gray overlay bars in **Figure 4** and **Figure 5**, such as 132 to 195). It is beyond the scope of this paper to catalog associations between our measurements and all other prior mutational studies of Env, but the concordance of our findings with the above mutational studies, and the fact that our data improve phylogenetic models of Env's natural evolution, suggest that our measurements authentically describe functional selection on Env.

Shifts in amino-acid preferences between BG505 and BF520

The most fundamental question that we seek to address is how similar the amino-acid preferences are between the two Envs. We have already noted that **Figure 3B** shows that the preferences are more correlated for replicate measurements on the same Env than for replicate measurements on different Envs. However, simply comparing correlation coefficients does not identify specific sites where mutational effects have shifted, nor does it quantify the magnitude of any shifts.

We therefore used a more rigorous approach to identify sites where the amino-acid preferences differ between BG505 and BF520 by an amount that exceeds the noise in our experiments. We first re-scaled the preferences from each experimental replicate by the stringency parameter for that Env from **Table 1** to calibrate all measurements to the stringency of natural selection. We then identified the 659 sites in the mutagenized regions of Env that are pairwise alignable between BG505 and BF520 (**Figure 6-source data 1**). For each site, we calculated the shift in amino-acid preferences between Envs using an approach similar to that of ? as illustrated in **Figure 6A**. This approach calculates the magnitude of the shift after correcting for experimental noise by comparing the differences in preferences between replicates for BG505 and BF520 to the differences between replicates for the same Env. **Figure 6A** shows this calculation for a site that has not shifted (site 598, which strongly prefers cysteine in both Envs), the most shifted site (512, which shifts from being mutationally tolerant in BG505 to strongly preferring alanine in BF520), and two other sites with more intermediate behaviors.

The overall distribution of shifts between BG505 and BF520 is shown in **Figure 6B**. Most sites have relatively small shifts (close to zero), although there is a long tail of sites with large shifts. This

Figure 4. Amino-acid preferences for the BG505 Env. At each site, the height of the letter is proportional for that site's preference for that amino acid. The top color bar indicates the region of Env (gp120 variable loop, gp120 not variable loop, or gp41). The lower color bar indicates the evidence that the site evolves faster ($\omega_r > 1$) or slower ($\omega_r < 1$) than expected given the experiments (see the last section of the Results and ??). We report the P -value for $\omega_r \neq 1$ rather than the value of ω_r itself since point estimates of ω_r are unreliable for individual sites due to low numbers of observations, making the P -value a better indicator of the strength of the statistical evidence for faster or slower than expected evolution (??). The letters above the logos indicate the wildtype amino acid in BG505. Sites are numbered using the HXB2 scheme (?). This logo plot shows the site-specific amino-acid preferences for BG505 after averaging the replicates and re-scaling by the stringency parameter in **Table 1**. The figure was generated using `dms_tools2` (?), https://jbloomlab.github.io/dms_tools2/, which in turn utilizes `weblogo` (?).

Figure 4-source data 1. The numerical values of the amino-acid preferences plotted in this figure are in `rescaled_BG505_prefs.csv`.

Figure 4-source data 2. The sequence of BG505 Env and mapping from sequential (*original* column) to HXB2 numbering (*new* column) is in `BG505_to_HXB2.csv`.

Figure 4-source data 3. The ω_r values and associated P -values for BG505 in HXB2 numbering are in `BG505_omegabySite.tsv`.

tail reaches its upper value with site 512, which has a shift of 0.52 out of a maximum possible of 1.0. How should we interpret this distribution – have mutational effects shifted a lot, or not very much? We can establish an upper-bound for how much sites might shift by comparing Env to a *non-homologous* protein. **Figure 6B** shows the distribution of shifts when comparing Env to influenza's hemagglutinin protein, which has previously had its amino-acid preferences measured

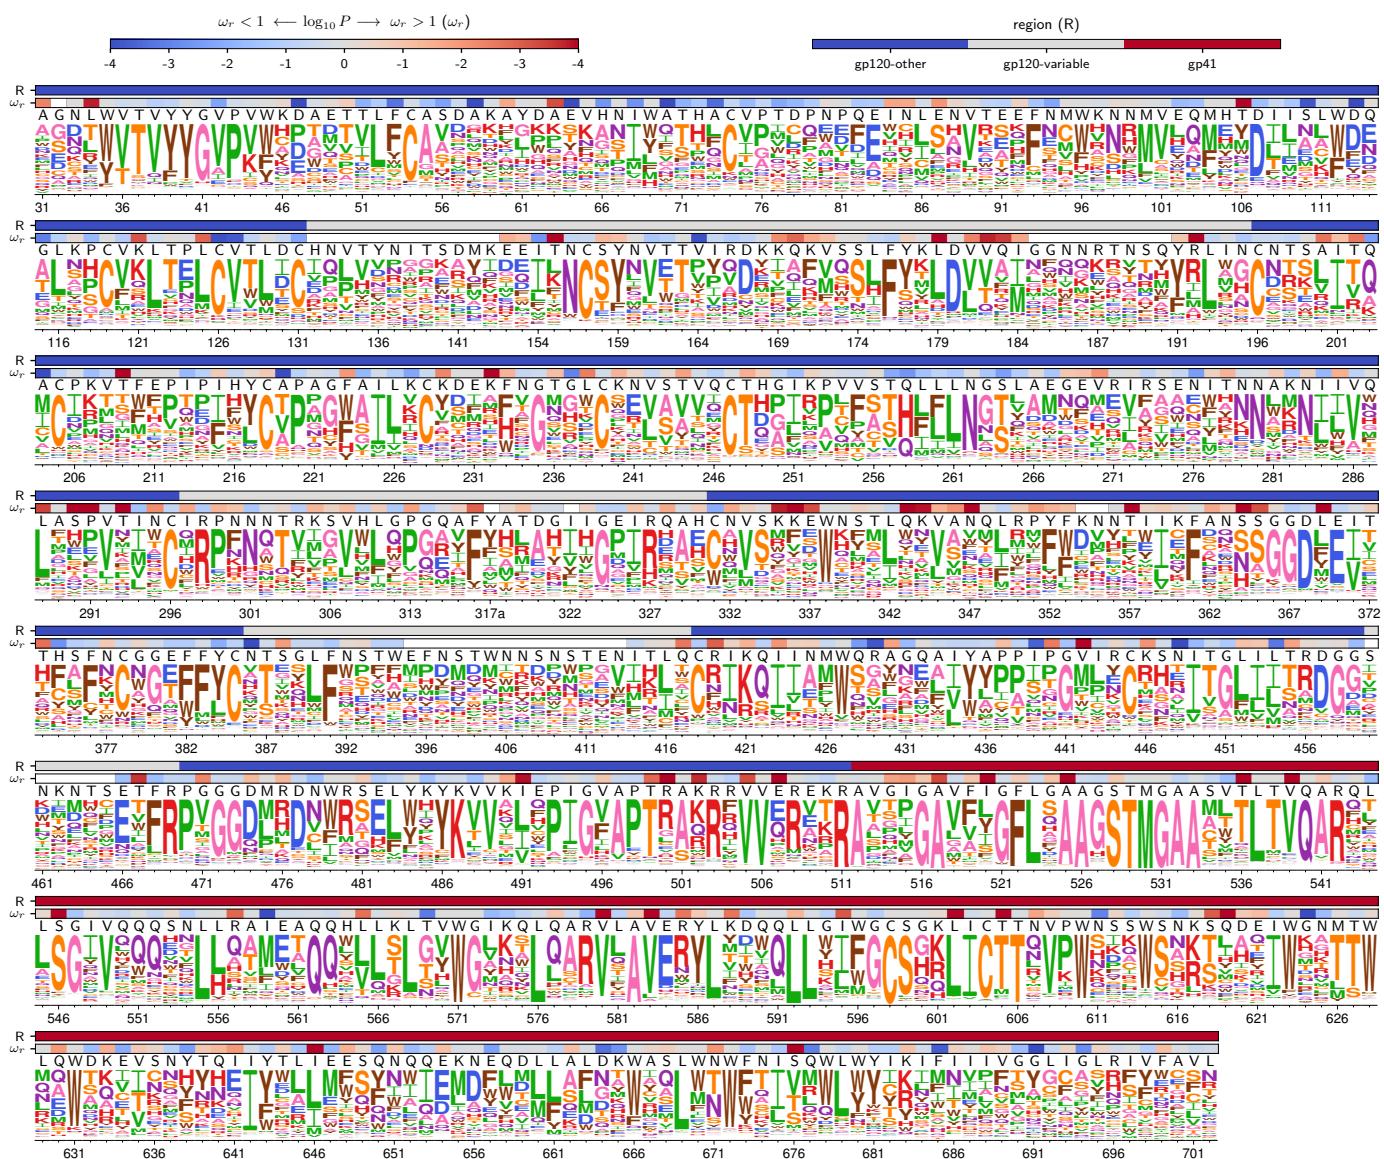

Figure 5. Amino-acid preferences for the BF520 Env. This figure is the same as **Figure 4** except that it shows the data for BF520 instead of BG505.

Figure 5-source data 1. The numerical values of the amino-acid preferences plotted in this figure are in `rescaled_BF520_prefs.csv`.

Figure 5-source data 2. The sequence of BF520 Env and mapping from sequential (*original* column) to HXB2 numbering (*new* column) is in `BF520_to_HXB2.csv`.

Figure 5-source data 3. The ω_r values and associated *P*-values for BF520 in HXB2 numbering are in `BG505_omegabySite.tsv`.

by deep mutational scanning (?). Most sites have large shifts between Env and hemagglutinin, with the typical shift being ~ 0.4 and some approaching the maximum value of 1.0. We can also establish a lower-bound by creating a null distribution for the expected shifts if all differences are simply due to experimental noise. This null distribution is created by randomizing the experimental replicates among Envs. **Figure 6B** shows that the null distribution is more peaked at zero than the real distribution, and does not have the same prominent tail of sites with large shifts. The answer to the question of how much mutational effects have shifted is therefore nuanced: they have substantially shifted at some sites, but remain vastly more similar between the two Envs than between two unrelated proteins.

We can use the null distribution to identify sites where the shifts between BG505 and BF520 are significantly larger than the noise in our experiments (**Figure 6B**). There are 30 such sites at

A

site	BG505 replicates	BF520 replicates	RMSD _{between} - RMSD _{within} = RMSD _{corrected}
598	CCC 1 2 3	CCC 1 2 3	0.04 0.03 0.01
528	SSS 1 2 3	SSS 1 2 3	0.35 0.19 0.16
288	FFF 1 2 3	LLL 1 2 3	0.73 0.27 0.46

B**C**

Figure 6. Env sites with shifted amino-acid preferences between BG505 and BF520. Note that the preferences have been re-scaled using the stringency parameters in **Table 1** to enable direct comparison across Envs. **(A)** Calculation of the corrected distance between the amino-acid preferences of BG505 and BF520 at four example sites. We have triplicate measurements for each Env. We calculate the distance between each pair of replicate measurements, and group these into comparisons *between* the two Envs and *within* replicates for the same Env. We compute the root-mean-square distance (RMSD) for both sets of comparisons, which we denote as RMSD_{between} and RMSD_{within}. The latter quantity is a measure of experimental noise. The noise-corrected distance between Envs at a site, RMSD_{corrected}, is simply the distance between the two Envs minus this noise. **(B)** The bottom distribution (orange) shows the corrected distances between BG505 and BF520 at all alignable sites. The next distribution (blue) is a null generated by computing the corrected distances on all randomizations of the replicates among Envs. The top two distributions (green) compare Env to the non-homologous influenza hemagglutinin (HA) protein (?) simply putting sites into correspondence based on sequence number. We compute the *P*-value that a site has shifted between BG505 and BF520 as the fraction of the null distribution that exceeds that shift, and identify significant shifts at a false discovery rate (FDR) of 0.1 using the method of ?. Using this approach, 30 of the 659 sites have significant shifts (corrected distance ≥ 0.22). **(C)** All sites that have significantly shifted their amino-acid preferences at an FDR of 0.01. For each site, the logo stacks show the across-replicate average preferences for BG505 and BF520. The wildtype amino acid for that Env is indicated using the small black letters above each logo plot; note how the wildtype amino acid is frequently but not always the most preferred one. The sites are sorted by the magnitude of the shift.

Figure 6-source data 1. The corrected distances between BG505 and BF520 at each site are in `BG505_to_BF520_prefs_dist.csv`.

a false discovery rate of 0.1. **Figure 6C** shows the amino-acid preferences of these significantly shifted sites for each Env. For the majority of shifted sites, one Env prefers a specific amino acid whereas the other Env tolerates many amino acids; for instance, see sites 512, 516, 599, 165, 605 and 505 in **Figure 6C**. Such broadening and narrowing of a site's mutational tolerance is frequently linked to changes in protein stability, with a more stable protein typically being more mutationally

tolerant (????). Work with engineered Env protein in the form of “SOSIP” trimer (??) has shown that BG505 SOSIP is more thermostable than BF520 SOSIP (?). Consistent with this fact, sites with altered mutational tolerance are often (although not always, see sites 165 and 520 in *Figure 6C*) more mutationally tolerant in BG505. Differences in Env’s expression level might also contribute to a general broadening or narrowing of tolerance to subsequent mutations. Because our experiments select for viral growth—which is affected by both Env function and expression—it is possible that some of the shifts are due to epistatic mutational effects on expression rather than function.

However, not all of the significantly shifted sites show a simple pattern of broadening or narrowing of mutational tolerance. For instance, site 288 does not alter its mutational tolerance but rather flips its rather narrow amino-acid preference from phenylalanine in BG505 to leucine in BF520 (*Figure 6C*). Thus, there is variation in both the extent and types of shifts observed.

Structural and evolutionary properties of shifted sites

What distinguishes the sites that have undergone significant shifts? First, we analyzed the distribution of shifted sites in context of Env’s three-dimensional structure. Env’s structure is highly conformationally dynamic and undergoes large changes upon receptor binding and membrane fusion. In an effort to account for these dynamics, we examined multiple conformational states of Env, including: the closed pre-fusion state ???, the open CD4-bound state ??, and the post-fusion six-helix bundle ????. *Figure 7A* shows the locations of the shifted sites on the crystal structure of Env in the closed pre-fusion state. There is no visually obvious tendency for shifted sites to preferentially be on Env’s surface or in its core, and statistical analysis of both the closed and open states of Env (*Figure 7B*) finds no association between a site’s relative solvent accessibility and whether its amino-acid preferences have shifted.

However, *Figure 7A* does suggest that the sites of significant shifts tend to cluster in Env’s structure, and a statistical analysis confirms that this is the case for both the closed and open states (*Figure 7C*). Therefore, the factors that drive shifts in Env’s mutational tolerance often affect physically interacting clusters of residues in a coordinated fashion. Moreover, these factors are present in multiple conformations of Env. We also investigated the distribution of shifted sites in context of the post-fusion six-helix bundle. However, only ~80 residues are resolved in this structure, and of these sites, only four have shifted amino-acid preferences. This low number of sites does not lend itself to statistical analysis, but a qualitative analysis of these sites on the structure revealed that three of the four shifted sites cluster at one end of the helical bundle (*Figure 7–Figure Supplement 2*).

An obvious hypothesis is that strongly shifted sites have substituted between BG505 and BF520, or physically contact such substitutions. According to this hypothesis, substitutions would alter the local physicochemical environment of the substituted site and its neighbors, thereby shifting the amino-acid preferences of sites in the physical cluster. But surprisingly, for both the closed and open conformations, the typical magnitude of shifts is not significantly larger at sites that have substituted, or at sites that contact sites that have experienced substitutions (*Figure 7D*). In the case of the six-helix bundle, there are a total of five structurally resolved substituted sites, one of which is adjacent to the cluster of shifted sites (*Figure 7–Figure Supplement 2*). The number of resolved shifted and substituted sites in this structure is too low for to perform the same statistical analysis as in *Figure 7D*. However, we found that the cluster of shifted and substituted sites in the six-helix bundle is also present in the closed and open states (*Figure 7–Figure Supplement 2*). Thus, this cluster is already well-accounted for by other states.

There is a borderline trend for the significantly shifted sites to be more likely to have substituted between BG505 and BF520 (*Figure 7–Figure Supplement 1*), but most shifted sites have not substituted (only 8 of the 30 shifted sites differ in amino-acid identity between the two Envs). The lack of strong enrichment in shifts at substituted sites contrasts with previous protein-wide experimental (?) and simulation-based (??) studies of shifting amino-acid preferences, which found that shifts were dramatically more pronounced at sites of substitutions. The difference may arise

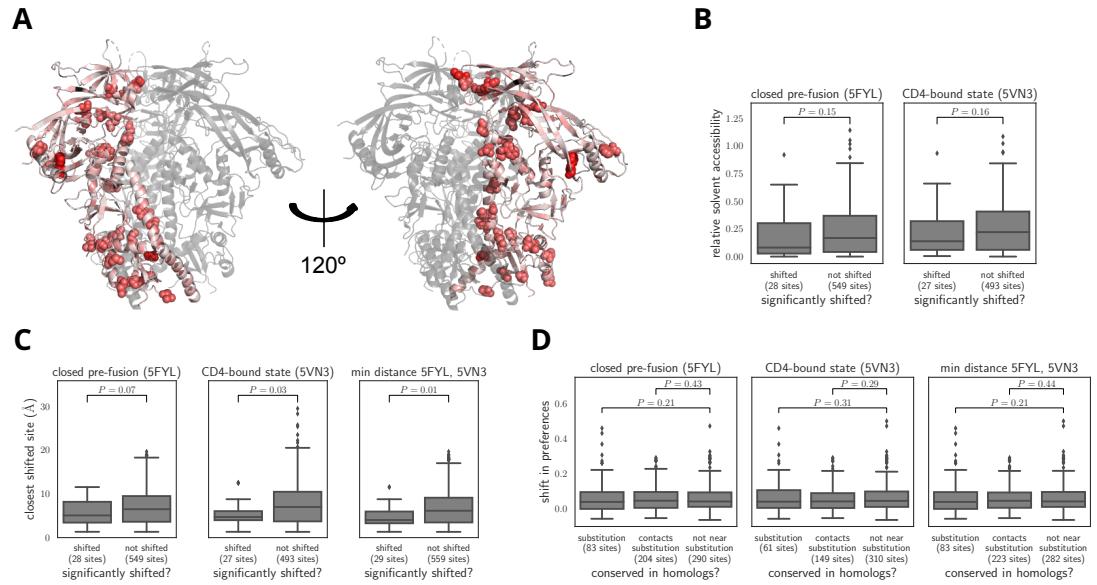

Figure 7. Characteristics of significantly shifted sites. **(A)** One monomer of the closed pre-fusion Env trimer (PDB 5FYL; ?) is colored from white to red according to the magnitude of the mutational shift at each site (red indicates large shift). Sites that are significantly shifted according to **Figure 6B** are in spheres, and all other sites are in cartoon representation. **(B)** There is no significant difference in the relative solvent accessibility of sites that have and have not undergone significant shifts. This observation holds for both the pre-fusion Env trimer in (A) and the CD4-bound Env trimer (PDB 5VN3; ?). The absolute solvent accessibility of each site was calculated using DSSP (?) and normalized to a relative solvent accessibility using the absolute accessibilities from ?. **(C)** Sites of significant shifts are clustered in the structures of both the closed and open Env trimers. The left two plots show the distance of each significantly shifted and not-shifted site to the closest other shifted site in the indicated structure. The right-most plot shows the minimum distance across both the closed and open conformations. The trend for shifts to cluster becomes stronger when considering the minimum distance, indicating that multiple conformations may shape this trend. **(D)** Large mutational shifts are *not* strongly enriched at sites that have substituted between BG505 and BF520, or at sites that contact sites that have substituted. The left-most plot shows the magnitudes of the shifts in context of the closed conformation of Env among the 83 crystallographically resolved sites that have substituted between BG505 and BF520, the 204 non-substituted sites that physically contact a substitution in this structure (any non-hydrogen atom within 3.5Å), and all other sites. The center plot shows these magnitudes in context of the open conformation, while the right-most plot shows these magnitudes when considering both the closed and open conformations, with the relative number of sites in each category shown in parentheses. In the right-most plot, non-substituted sites are considered to be contacting a substitution if they do so in at least one structural context. **Figure 7-Figure Supplement 1** shows that there is a modest borderline-significant tendency of significantly shifted sites to have substituted. All panels only show the 577 and 520 sites that are resolved in the structures of the closed and open conformations, respectively. Of the 30 significantly shifted sites in **Figure 6B**, only 28 and 27 are structurally resolved in the closed and open conformations, respectively. Structural distances and solvent accessibilities were calculated using all monomers in the trimer. *P* values were calculated using the Mann-Whitney *U* test.

Figure 7-Figure supplement 1. Statistical testing of whether significantly shifted sites are more likely to have substituted between BG505 and BF520.

Figure 7-Figure supplement 2. Cluster of shifted sites in the post-fusion six-helix bundle of Env.

Figure 7-Figure supplement 3. Clusters of shifted sites in highly dynamic regions of Env.

because these earlier studies examined proteins that are fairly conformationally static (absolutely so in the case of the simulations). On the other hand, as stated above, Env is extremely complex and conformationally dynamic (??), which may increase the opportunities for long-range epistasis to enable substitutions at one site to shift the amino-acid preferences of distant sites.

Indeed, many of the shifted sites cluster within regions of Env that are both highly dynamic. **Figure 7-Figure Supplement 3** shows the structural context of these clusters in finer detail. One cluster is at the trimer apex where two of Env's variable loops pack against one another and against

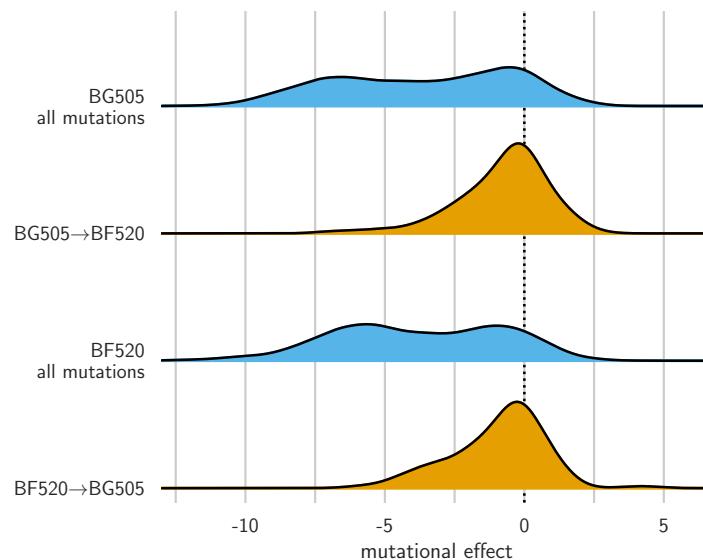

Figure 8. Entrenchment of substitutions during Env evolution. There are 12,521 possible amino-acid mutations at the 659 mutagenized sites alignable between BG505 and BF520. The blue densities show the effects of all these mutations to each Env. The orange densities show the effects of just the 92 mutations that convert BG505 to BF520 or vice versa. In the absence of entrenchment, mutating a site in BG505 to its identity in BF520 should have the opposite effect of mutating the site in BF520 to its identity in BG505. In this case, we would expect the BF520→BG505 distribution to be the mirror image of the BG505→BF520 distribution – and both distributions should be centered around zero if the two Envs are equivalently functional. Instead, mutating a site in either Env to its identity in the other Env tends to be deleterious, indicating that substitutions are often entrenched in the Env in which they have fixed. The effect of a mutation is quantified as the log of the ratio of the site's preference for the mutant amino acid to the preference for the wildtype amino acid.

an adjacent protomer. Upon CD4 binding, these loops become highly disordered ???. Mutations at two of the shifted sites in this cluster (165 and 307) have been shown to cause Env to assume aberrant conformations, suggesting that these sites can strongly modulate Env's dynamics ?. The other cluster of shifted sites is near a network of hydrophobic amino acids that has been proposed to help transmit the large conformational change that takes place upon CD4 binding ?. One of the shifted sites (69) overlaps with this network, and mutations at another (64) have been shown to strongly modulate the relative stability of the open and closed conformations ?. In total, these two clusters consist of nearly half (13/30) of the shifted sites. One hypothesis as to why so many shifted sites cluster in these regions is that the dynamic nature of these regions allows long-range epistatic interactions to be readily propagated between shifted and substituted sites that are distant from one another. Indeed, as shown in *Figure 7–Figure Supplement 3*, these dynamic regions also contain several substituted sites. However, due to the complexity of Env's dynamics, it is difficult to discern exactly how these interactions might occur.

Entrenchment of substitutions modestly contributes to mutational shifts

One idea that has recently gained support in the protein-evolution field is that substitutions become “entrenched” by subsequent evolution (???). Entrenchment is the tendency of a mutational reversion to become increasingly unfavorable as a sequence evolves. Given two homologs, if there is no entrenchment then the effect of mutating a site in the first homolog to its identity in the second will simply be the opposite of mutating the site in the second homolog to its identity in the first. But if there is entrenchment, then both mutations will be unfavorable, since the site is entrenched at its preferred identity in each homolog.

Figure 8 shows the distribution of effects for mutating all sites that differ between BG505 and BF520 to the identity in the other Env. As expected under entrenchment, the average effect

of these mutations is deleterious – although there are a substantial number of sites where the mutational flips are not deleterious. We can get some sense of the magnitude of the entrenchment by comparing the effects of the BG505↔BF520 mutations to the distribution of effects of all possible amino-acid mutations (*Figure 8*). This comparison shows that even unfavorable inter-Env mutational flips are generally more favorable than random amino-acid mutations. Therefore, entrenchment occurs for some but not all substitutions that distinguish BG505 and BF520, and the magnitude of entrenchment is less than the effect of a typical random mutation. Entrenchment of substitutions therefore contributes to some of the mutational shifts. But given that many of these shifts occur at sites that do not even differ between the Envs (*Figure 7D*), entrenchment of substitutions is clearly not the only cause of the shifting amino-acid preferences.

Comparing selection in the lab to natural selection

Our experiments measure the effects of mutations on viral growth in a T-cell line in the lab. But HIV actually evolves in humans, where additional selection pressures on Env are undoubtedly present. For instance, antibody pressure might increase the rate of evolution at some sites (??), whereas pressure to mask certain epitopes (?) might add constraint at other sites. Comparing selection in our experiments to natural selection can identify sites that are under such additional pressures during HIV's actual evolution in humans.

We determined whether each site in Env evolves faster or slower in nature than expected given three models: that evolution is purely neutral (all nonsynonymous and synonymous mutations have equivalent effects), that sites are under the protein-level constraint measured in our experiments with BG505, or that sites are under the constraint measured with BF520. The first model used a standard dN/dS test (the “FEL” method of ?), whereas the other two models are conceptually similar but account for the experimentally measured amino-acid preferences as described by ?. All three models test if individual sites evolve faster or slower than expected, but they “expect” different things: the dN/dS model expects nonsynonymous and synonymous mutations fix at the same rate, while the ExpCM expects the rate at a site to depend on the experimentally measured functional constraints. In all cases, the evidence that a site r evolves differently than expected is statistically summarized by the P -value that ω_r is $>$ or $<$ 1. The standard dN/dS model finds hundreds of sites that evolve slower than expected under neutral evolution (*Table 1*, $\omega_r < 1$), and only a handful of sites that evolve faster than expected under neutral evolution (*Table 1*, $\omega_r > 1$). This finding is unsurprising, since it is well known that Env is under functional constraint. In contrast, ExpCM's that test the rates of evolution relative to the experimentally measured constraints find far fewer sites that evolve slower than expected, but many more sites that evolve faster (*Table 1*).

The sites that evolve slower or faster than expected from the experiments are shown in *Figure 9A,B*, and overlaid on the logoplots in *Figure 4* and *Figure 5* as the ω_r values. The identified sites are similar regardless of whether we use the experiments with BG505 or BF520 (*Figure 9C*). The reason the results are similar for both experimental datasets is that (as discussed above) the amino-acid preferences of *most* sites are similar in both Envs, suggesting that either dataset provides a reasonable approximation of the site-specific functional constraints across the clade A Envs in *Figure 1*.

What causes some sites to evolve faster or slower in nature than expected from the experiments? The answer in both cases is likely to be immune selection. Most of the sites of faster-than-expected evolution are on the surface of Env (*Figure 9A,B* and *Figure 9–Figure Supplement 1*). Env's escape from autologous neutralizing antibodies often involves amino-acid substitutions in surface-exposed regions (?), including at many of the sites that evolve faster than expected. Since our deep mutational scanning did not impose antibody pressure, sites where substitutions are antibody-driven will evolve faster in nature than expected from the experiments.

Interestingly, immune selection also offers a plausible explanation for the sites that evolve *slower* than expected. In addition to escaping immunity via substitutions at antibody-binding footprints, Env is notorious for employing a range of more general strategies to reduce its susceptibility to

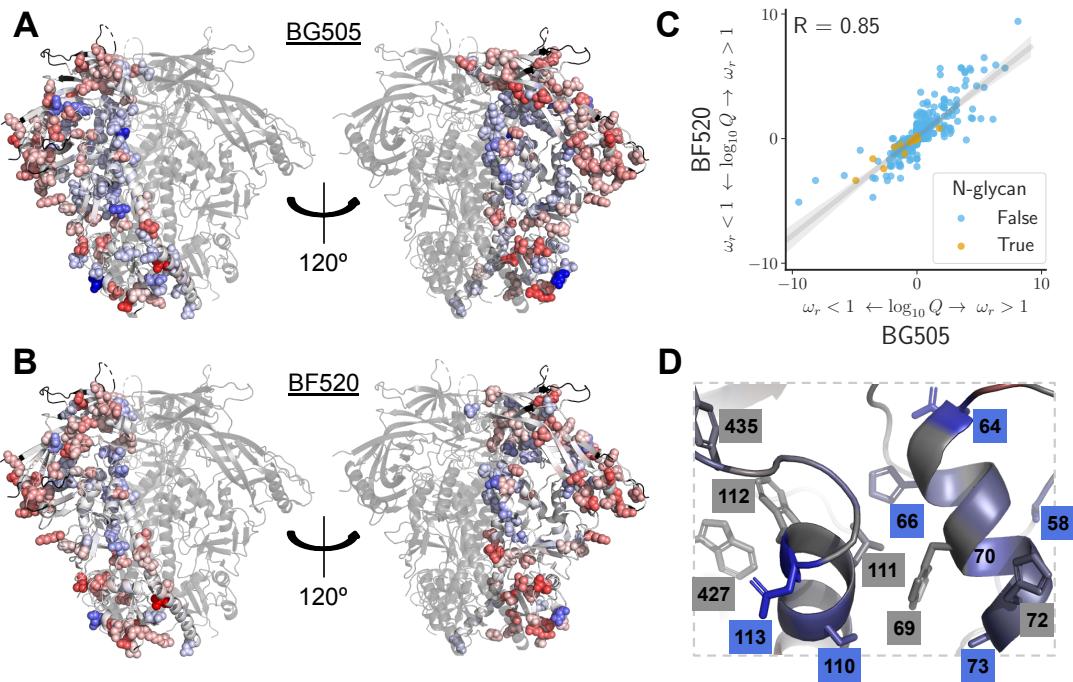

Figure 9. Sites in Env that evolve faster or slower in nature than expected given the functional constraints measured in the lab. We calculated the statistical evidence that each site evolves faster ($\omega_r > 1$) or slower ($\omega_r < 1$) than expected given the experimentally measured amino-acid preferences using the method of **?**. **(A)** One monomer of the Env trimer (PDB 5FYL; **?**) is colored from blue to white to red based on the strength of evidence that sites evolve slower than expected (blue), as expected (white) or faster than expected (red) given the BG505 experiments. Sites where the rate of evolution is significantly different than expected at a false discovery rate of 0.05 are shown in spheres. **(B)** Like (A) but using the data from the BF520 experiments. For both Envs, sites that evolve significantly slower or faster than expected are often on Env's surface (**Figure 9-Figure Supplement 1**). **(C)** The results are similar regardless of whether the BG505 or BF520 experiments are used. Many of the sites of slower-than-expected evolution are asparagines in N-linked glycosylation motifs (**Figure 9-Figure Supplement 2**). All sites that evolve slower than expected for both experimental datasets are in **Figure 9-Figure Supplement 3**. **(D)** A large cluster of sites that evolve slower than expected is likely involved in Env's transition between open and closed conformational states. Gray boxes indicate sites that **?**, PDB 5VN3 proposed form a hydrophobic network that regulates the conformational change; blue boxes and sticks indicate sites that evolve slower than expected. The color spectrum is similar to the one in (A) and (B), but is colored from blue to grey to red for increased visibility of the grey residues in the hydrophobic network. All analyses used the phylogenetic tree in **Figure 1**.

Figure 9-Figure supplement 1. Relative solvent accessibilities of sites evolving faster or slower than expected.

Figure 9-Figure supplement 2. Amino-acid preferences and alignment frequencies for glycosylation motifs.

antibodies. These strategies include shielding immunogenic regions with glycans (???) or hiding them by adopting a closed protein conformation (???). Sites that contribute to such general immune-evasion strategies will be under a constraint in nature that is not present in our experiments – and indeed, such sites evolve more slowly than expected from our experiments. For instance, we find very little selection to maintain most glycans in our cell-culture experiments. Of the 21 N-linked glycosylation sites shared between BG505 and BF520, only four are under strong selection to maintain the glycan in our experiments – despite the fact that most are conserved in nature (**Figure 9C** and **Figure 9-Figure Supplement 2**). This finding concords with prior literature suggesting that these glycans are selected primarily for their role in immune evasion (???). Similarly, a network of sites that help regulate Env's transition between open and closed conformations that have

different antibody susceptibilities (**Figure 9D**) also evolve slower in nature than expected from our experiments. Therefore, we can distinguish evolutionary patterns that are shaped by simple selection for Env function from those that are due to the additional complex pressures imposed during human infections.

Discussion

We have experimentally measured the preference for each amino acid at each site in the ectodomain and transmembrane domain of two Envs under selection for viral growth in cell culture. These amino-acid preference maps are generally consistent with prior knowledge about sites that are important for protein properties such as receptor binding or disulfide-mediated stability. However, the main value of these maps comes not from comparing them with prior knowledge, but from the fact that such prior knowledge encompasses just a small fraction of the vast mutational space available to Env. Because Env evolves so rapidly, every study of this protein must be placed in an evolutionary context, and our comprehensive amino-acid preference maps potentially enable this in ways that prior piecemeal studies of mutations cannot.

But these maps come with a potentially serious caveat: each one is measured for just a single Env variant. The major question that our study aimed to answer is whether the maps are still useful for evolutionary questions, or whether Env's amino-acid preferences shift so rapidly that each map only applies to the specific HIV strain for which it was measured. This question is reminiscent of one that was grappled with in the early days of protein crystallography, when it first became possible to build maps of a protein's structure. Because it was not (and is still not) possible to crystallize every variant of a protein, it was necessary to determine whether protein structures could be usefully generalized among homologs. Fortunately for the utility of structural biology, it soon became apparent that closely homologous proteins have similar structures (??). This rough generalizability of protein structures holds even for a protein as conformationally complex as Env – for although there are many examples of mutations that alter aspects of Env's conformation and dynamics (????), SOSIP trimer structures from diverse Env strains remain highly similar in most respects (????).

Our results show that amino-acid preference maps of Env also have a useful level of conservation for many purposes. From a qualitative perspective, the amino-acid preferences look mostly similar between BG505 and BF520, and so provide a valuable reference for estimating which mutations are likely to be tolerated at each site in diverse HIV strains. Indeed, we anticipate that the complete maps of mutational effects in **Figure 4** and **Figure 5** will be useful for future sequence-structure-function studies. From an analytical perspective, a powerful use of our maps is to identify sites that evolve differently in nature than is required by the simple selection for viral growth imposed in our experiments – and the identified sites are largely the same regardless of whether the analysis uses an amino-acid preference map from BG505 or BF520.

Of course, from the perspective of protein evolution, the most interesting sites are the exceptions to the general conservation of amino-acid preferences. Consistent with studies of other proteins (????), we find a subset of sites that change markedly in which mutations they tolerate. Some shifted sites simply accommodate more amino acids in the more stable BG505 Env – a type of shift that has been well-documented for other proteins (????). But interestingly, there is no strong trend for shifts to be enhanced at sites that differ between BG505 and BF520. Recent studies of protein evolution have focused on the idea that substitutions become “entrenched” as sites shift to accommodate new amino acids (????). Indeed, a prior protein-wide comparison of amino-acid preferences across homologs of influenza nucleoprotein found a significant enrichment of shifts at sites of substitutions (?). But although there is some entrenchment of differences between BG505 and BF520, this is not the major factor behind the shifts in amino-acid preferences: the majority of sites that have shifted between BG505 and BF520 actually have the same wildtype amino acid in both Envs even though the preferences have shifted. This rather surprising result might be due to Env's exceptional conformational complexity – mutations can cause long-range alterations in Env's

conformation (????), so it seems plausible that they might also shift mutational tolerance at distant sites. Regardless of the exact mechanism, our large-scale datasets of mutational effects in multiple viral strains should be useful for efforts to computationally parameterize “fitness landscapes” of Env (????).

Our experiments provide highly quantitative data on the mutational tolerance of Env under selection for viral growth in cell culture. These data are amenable to rigorous functional and evolutionary analyses. Here we have shown how these data can be compared between Envs to identify sites where mutational tolerance shifts with viral genotype, or between experiments and nature to identify sites under different pressure in the lab and in humans. Future experiments that modulate selection pressures in other relevant ways should provide further insight into the forces that drive and constrain HIV’s evolution.

Methods and Materials

Creation of codon-mutant libraries

Our codon mutant libraries mutagenized all sites in *env* to all 64 codons, except that the signal peptide and cytoplasmic tail were not mutagenized. The rationale for excluding these regions is that they are not part of Env's ectodomain, and are prone to mutations that strongly modulate Env's expression level (??).

The codon-mutant libraries were generated using the approach originally described in ?, with the modification of ? to ensure more uniform primer melting temperatures. The computer script used to design the mutagenesis primers (along with some detailed implementation notes) is at <https://github.com/jbloomlab/CodonTilingPrimers>. For BF520, the three libraries are the same ones described by ?. For BG505, we created three libraries for this study. The wildtype BG505 sequence used for these libraries is in Supplemental file 3. The BG505 mutagenesis primers are in Supplemental file 4.

The end primers for the BG505 mutagenesis were: 5'-tgaaggcaaaactactggccgtctcgagcagaagacagtggcaatgaga-3' and 5'-gctacaaaatgcataacacgcgtctcattttccctaaccctcaggcca-3'. As with BF520, we cloned the BG505 *env* libraries into the *env* locus of the full-length proviral genome of HIV strain Q23 (another subtype-A transmitted/founder virus; ?) using the high-efficiency cloning vector described in ?. For this cloning, we digested the cloning vector with BsmBI, and then used PCR to elongate the amplicons to include 30 nucleotides at each end that were identical in sequence to the ends of the BsmBI-digested vector. The primers for this PCR were: 5'-agataggtaattgagagaataagagaaaag cagaagacagtggcaatgagagtatgg-3' and 5'-ctcctggtgctgctggaggggcacgttcattttccctaaccctcaggccatc-3'. Next, we used NEBuilder HiFi DNA Assembly (NEB, E2621S) to clone the *env* amplicons into the BsmBI-digested plasmids. We purified the assembled products using Agencourt AMPure XP beads (Beckman Coulter, A63880) using a bead-to-sample ratio of 1.5, and then transformed the purified products into Stellar electrocompetent cells (Takara, 636765). The transformations yielded between 1.5-3.6 million unique clones for each of the three replicate libraries, as estimated by plating 1:2,000 dilutions of the transformations. We scraped the plated colonies and maxiprepped the plasmid DNA; unlike in ?, we did not include a 4-hour outgrowth step after the scraping step. For the wildtype controls, we maxiprepped three independent cultures of wildtype BG505 *env* cloned into the same Q23 proviral plasmid. See **Figure 2–Figure Supplement 1** and **Figure 3A** for information on the average mutation rate in these libraries as estimated by Sanger sequencing and deep sequencing, respectively.

Generation and passaging of viruses

For BG505, we generated mutant virus libraries from the proviral plasmid libraries by transfecting 293T cells in three 6-well plates (so 18 wells total per library) with a per-well mixture of 2 μ g plasmid DNA, 6 μ l FuGENE 6 Transfection Reagent (Promega, E269A), and 100 μ l DMEM. The 293T cells were seeded at 5×10^5 cells/well in D10 media (DMEM supplemented with 10% FBS, 1% 200 mM L-glutamine, and 1% of a solution of 10,000 units/mL penicillin and 10,000 μ g/mL streptomycin) the day before transfection, such that they were approximately 50% confluent at the time of transfection. In parallel, we generated wildtype viruses by transfecting one 6-well plate of 293T cells with each wildtype plasmid replicate. At 2 days post-transfection, we harvested the transfection supernatant, passed it through a 0.2 μ m filter to remove cells, treated the supernatant with DNase to digest residual plasmid DNA as in ?, and froze aliquots at -80°C. We thawed and titered aliquots using the TZM-bl assay in the presence of 10 μ g/mL DEAE-dextran as described in ?.

We conducted the low MOI viral passage illustrated in **Figure 2A** in SupT1.CCR5 cells (obtained from Dr. James Hoxie; ?). During this passage, cells were maintained in R10 media, which has the same composition as the D10 described above, except RPMI-1640 (GE Healthcare Life Sciences, SH30255.01) is used in the place of DMEM. In addition, the media contained 10 μ g/mL DEAE-dextran to enhance viral infection. We infected cells with 4 million (for replicate 1) or 5 million (for

replicates 2 and 3) TZM-bl infectious units of mutant virus at an MOI of 0.01, with cells at a starting concentration of 1 million cells/mL in vented tissue-culture flasks (Fisher Scientific, 14-826-80). At day 1 post-infection, we pelleted cells, aspirated the supernatant, and resuspended cell pellets in the same volume of fresh media still including the DEAE-dextran. At 2 days post-infection, we doubled the volume of each culture with fresh media still including DEAE-dextran. At 4 days post-infection, we pelleted cells, passed the viral supernatant through a $0.2\text{ }\mu\text{m}$ filter, concentrated the virus ~30 fold using ultracentrifugation as described in ?, and froze aliquots at -80°C. In parallel, for each replicate, we also passaged 2×10^5 (for replicate 1) or 5×10^5 (for replicates 2 and 3) TZM-bl infectious units of wildtype virus using the same procedure. To obtain final titers for our concentrated virus, we thawed one of the aliquots stored at -80°C and titered using the TZM-bl assay in the presence of 10 $\mu\text{g}/\text{mL}$ DEAE-dextran.

For the final short-duration infection illustrated in *Figure 2A*, for each replicate we infected 10^6 TZM-bl infectious units into 10^6 SupT1.CCR5 cells in the presence of 100 $\mu\text{g}/\text{mL}$ DEAE-dextran (note that this is a 10-fold higher concentration of DEAE-dextran than for the other steps, meaning that the effective MOI of infection is higher if DEAE-dextran has the expected effect of enhancing viral infection). Three hours post-infection, we pelleted the cells and resuspended them in fresh media without any DEAE-dextran. At 12 hours post-infection, we pelleted cells, washed them once with PBS, and then used a miniprep kit to harvest reverse-transcribed unintegrated viral DNA (?).

The generation, passaging and deep sequencing of BF520 was done in a highly similar fashion, except that we only had a single replicate of the wildtype control. Note that the final passaged BF520 mutant libraries analyzed here actually correspond to the “no-antibody” controls described in ?, but that study did not analyze the initial plasmid mutant libraries relative to these passaged viruses, and so was not able to provide measurements of the amino-acid preferences.

Illumina deep sequencing

We deep sequenced all of the samples shown in *Figure 3A*: the plasmid mutant libraries and wildtype plasmid controls, and the cDNA from the final mutant viruses and wildtype virus controls. In order to increase the sequence accuracy, we used a barcoded-subamplicon sequencing strategy. This general strategy was originally applied in the context of deep mutational scanning by ?, and the specific protocol used in our work is described in ? (see also https://jbloomlab.github.io/dms_tools2/bcsubamp.html).

The primers used for BG505 are in Supplementary file 5. The primers used for BF520 are in ?. The data generated by the Illumina deep sequencing are on the Sequence Read Archive under the accession numbers provided at the beginning of the Jupyter notebook in Supplementary files 1 and 2.

Analysis of deep-sequencing data

We analyzed the deep-sequencing data using the `dms_tools2` software package (?; https://jbloomlab.github.io/dms_tools2/, version 2.2.4). The algorithm that goes from the deep-sequencing counts to the amino-acid preferences is that described in ? (see also https://jbloomlab.github.io/dms_tools2/prefs.html). A Jupyter notebook that performs the entire analysis including generation of most of the figures in this paper is in Supplementary file 1. An HTML rendering of this notebook is in Supplementary file 2.

The Jupyter notebooks in Supplementary files 1 and 2 also contain numerous plots that summarize relevant aspects of the deep sequencing such as read depth, per-codon mutation frequency, mutation types, etc. Supplementary file 1 also contains text files and CSV files with the numerical values shown in these plots.

Citations are also owed to `weblogo` (?; <http://weblogo.threplusone.com/>) and `ggseqlogo` (?; <https://omarwagih.github.io/ggseqlogo/>), which were used in the generation of the logoplots.

Alignments and phylogenetic analyses of Env sequences

A basic description of the process used to generate the clade A sequence alignment in **Figure 1**-source data 1, the alignment mask in **Figure 1**-source data 2, and the phylogenetic tree in **Figure 1** are provided in the legend to that figure. An algorithmic description of how the alignment and tree were generated are in Supplementary files 1 and 2.

For fitting of the phylogenetic substitution models, we used `phydms` (?; <http://jbloomlab.github.io/phydms/>, version 2.2.1) to optimize the substitution model parameters and branch lengths on the fixed tree topology in **Figure 1**. The Goldman-Yang (or YNGKP) model used in **Table 1** is the M5 variant described by ?, with the equilibrium codon frequencies determined empirically using the CF3x4 method (?). For the ExpCM shown in **Table 1**, we extended the models with empirical nucleotide frequencies described in ? to also allow ω to be drawn from discrete gamma-distributed categories exactly as for the M5 model. These ExpCM with gamma-distributed ω were implemented in `phydms` using the equations provided by ? (see also <http://jbloomlab.github.io/phydms/implementation.html#models-with-a-gamma-distributed-model-parameter>). The preferences were re-scaled by the stringency parameters in **Table 1** as described in ?. For both the M5 model and the ExpCM with a gamma-distributed ω , we used four categories for the discretized gamma distribution.

Table 1-source-data 1 shows the results for a wider set of models than those used in **Table 1**. These include the M0 model of ?, ExpCM without a gamma-distributed ω , and ExpCM in which the amino-acid preferences are averaged across sites as a control to ensure that the improved performance of these models is due to their site-specificity. Note how for these Env alignments, using a gamma-distributed ω is very important in order for the ExpCMs to outperform the M5 model – we suspect this is because there are many sites of strong diversifying selection.

For detection of sites with faster or slower than expected evolution, we used the approach in ?, which is exactly modeled on the FEL approach of ? but extended to ExpCM. This approach estimates a *P*-value that ω_r is not equal to one for each site r using a likelihood-ratio test. The actual point estimates of ω_r are unreliable for individual sites due to the limited number of observations, so we report the *P*-value that ω_r is not equal to one, which is a better indication of the strength of the statistical evidence for faster or slower than expected evolution (??). For the Q-values and false discovery rate testing, we considered the tests for $\omega_r > 1$ and $\omega_r < 1$ separately.

Supplementary files 1 and 2 contains the code that runs `phydms` to reproduce all of these analyses.

Re-scaling the preferences

The amino-acid preferences that are directly extracted from the deep sequencing data essentially give the enrichment / depletion of each mutation, normalized to sum to one at each site (?; https://jbloomlab.github.io/dms_tools2/prefs.html). However, the extent that any mutation is enriched or depleted is a combination of two factors: the inherent effect of that mutation, and the “stringency” of the experimental selection. For instance, if the selection is weak, then deleterious mutations will only be slightly depleted; conversely, if selection is strong, then deleterious mutations will be greatly depleted. The fact that the preferences depend on the stringency of the experimental selection is important if we want to compare results between Envs. The reason is that our goal is to identify differences in the inherent effects of mutations between Envs, not simply find differences due to variation in experimental stringency. Of course, we have done our best to perform the experiments for BG505 and BF520 equivalently, but because these are different viruses with different growth rates, it is impossible to exactly match the experimental stringencies. This can be seen in **Figure 3–Figure Supplement 1**, which shows that stop codons were more depleted for BG505 than BF520, indicating that selection in our experiments was more stringent for BG505.

How should we best re-scale the preferences? Raising them to a power is a sensible approach. To see why, imagine a mutation that is depleted 3-fold after 2 rounds of viral growth. If our experiment instead allowed $2^2 = 4$ rounds of viral growth, then the mutation would be depleted $3^2 = 9$ -fold. More generally, if a mutation is enriched in frequency by ϕ -fold after n rounds of viral growth,

then it will be enriched in frequency by ϕ^β -fold after $\beta \times n$ rounds of viral growth. Since the amino-acid preferences are conceptually equivalent to the re-normalized enrichments of mutations (?), (https://jbloomlab.github.io/dms_tools2/prefs.html), it therefore makes sense that the re-scaled preference $\pi_{r,a}$ for amino-acid a at site r should be related to the directly measured preference $\hat{\pi}_{r,a}$ by $\pi_{r,a} \propto (\hat{\pi}_{r,a})^\beta$. And indeed, this is exactly the re-scaling scheme described in ? that we use to re-scale our preferences for BG505 and BF520.

The last point is how to choose the re-scaling parameter β for each Env. It turns out that the features that we have described above for our experiments are also a feature of natural evolution: the expected frequency of a substitution during evolution depends not only on the inherent fitness effect of that mutation, but also on the effective population size, which is conceptually somewhat similar to the stringency of selection. It turns out that in a mutation-selection phylogenetic model of evolution, if the amino-acid preferences are taken to represent the “fitness effects” of mutations, then the exponential scaling parameter β is proportional to the effective population size (??). Therefore, fitting the β parameter using a phylogenetic approach enables standardization of the preferences for the two Envs, and re-scales the preferences so that they best match with the actual stringency of selection observed in nature (?).

Note that in practice this re-scaling scheme is roughly equivalent to a more heuristic approach that has been used by ? and others. In this heuristic approach, the log-transformed enrichment ratios from different experiments are adjusted so that the distributions have equal spreads. Since multiplying log-transformed enrichment ratios is equivalent to exponentiating amino-acid preferences, these two re-scaling procedures apply the same mathematical transformation.

Identifying sites of shifted amino-acid preference

When identifying shifts in amino-acid preferences between the two Envs, we needed a way to quantify differences between the Envs while accounting for the fact that our measurements are noisy. The approach we use is based closely on that of ?, and is illustrated graphically in **Figure 6A**. The RMSD_{corrected} value is our measure of the magnitude of the shift. **Figure 6A**, its legend, and the associated text completely explains these calculations with the following exception: they do not detail how the “distance” between any two preference measurements was calculated. The distance between preferences at each site was simply defined as half of the sum of absolute value of the difference between preferences for each amino acid. Specifically, for a given site r , let $\pi_{r,a}^i$ be the re-scaled preference for amino-acid a in homolog i (e.g., BG505) and let $\pi_{r,a}^j$ be the re-scaled preference for that same amino acid in homolog j (e.g., BF520). Then the distance between the homologs at this site is simply $D_r^{i,j} = \frac{1}{2} \sum_a |\pi_{r,a}^i - \pi_{r,a}^j|$. The factor of $\frac{1}{2}$ is used so that the maximum distance will always fall between zero and one.

Analysis of entrenchment

For the analysis in **Figure 8**, the results are presented in terms of the mutational effects rather than the amino-acid preferences. If $\pi_{r,a}$ is the preference of site r for amino-acid a and $\pi_{r,a'}$ is the preference for amino-acid a' (both re-scaled by the stringency parameters in **Table 1**), then the estimated effect of the mutation from a to a' is simply $\log\left(\frac{\pi_{r,a'}}{\pi_{r,a}}\right)$.

Data and code availability

All code and input data required to reproduce all analyses in this paper are in Supplementary file 1 (see also Supplementary file 2). The deep sequencing data are on the Sequence Read Archive with the accession numbers listed in Supplementary files 1 and 2.

Acknowledgments

We thank Michael Doud and Orr Ashenberger for computer code that formed the basis for some of the analyses. We thank Andrew Ward for pointing out to us that some of the sites with slower-than-expected rates of evolution are involved in Env's conformational changes upon receptor binding.

We thank Kelly Lee for helpful input about the relative stabilities of the BG505 and BF520 Envs. We thank the Fred Hutch Genomics Core for performing the Illumina deep sequencing.

Supplementary file 1. The code to perform all steps in the analysis is in `analysis_code.zip`. Specifically, this file contains a Jupyter notebook that performs the analysis, all required input data, and all reasonably sized output files. The Jupyter notebook downloads the deep sequencing data, processes it with the `dms_tools2` software (? , https://jbloomlab.github.io/dms_tools2/), and also performs a variety of downstream analyses that generate most of the figures for this paper.

Supplementary file 2. An HTML rendering of the Jupyter notebook that performs the computational analysis. The actual notebook is in Supplementary file 1, but if you just want to look at the analysis rather than run it, then you may prefer this file instead. In particular, the notebook contains plots detailing the deep sequencing data analysis as generated using the `dms_tools2` software (? , https://jbloomlab.github.io/dms_tools2/).

Supplementary file 3. The sequence of the wildtype BG505 *env* used in our study is in FASTA format in the file `BG505_env.fasta`.

Supplementary file 4. The sequences of the primers used for the BG505 codon mutagenesis are in the file `BG505_codon_mutagenesis_primers.txt`.

Supplementary file 5. The primers used for the BG505 barcoded-subamplicon sequencing are in the file `BG505_bcsubamp_primers.txt`.

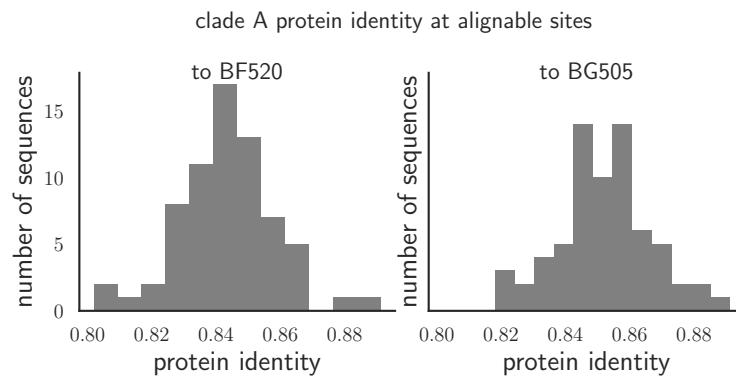

Figure 1-Figure supplement 1. The histograms show the pairwise amino-acid identity of each Env to all other sequences in the clade A alignment in **Figure 1**-source data 1 after masking the sites delineated in **Figure 1**-source data 2. There are 616 non-masked sites. The pairwise protein identity between BG505 and BF520 is 86.2% (721 of 836 sites identical) when considering *all* sites, and 89.1% (549 of 616 sites identical) when considering just the non-masked sites.

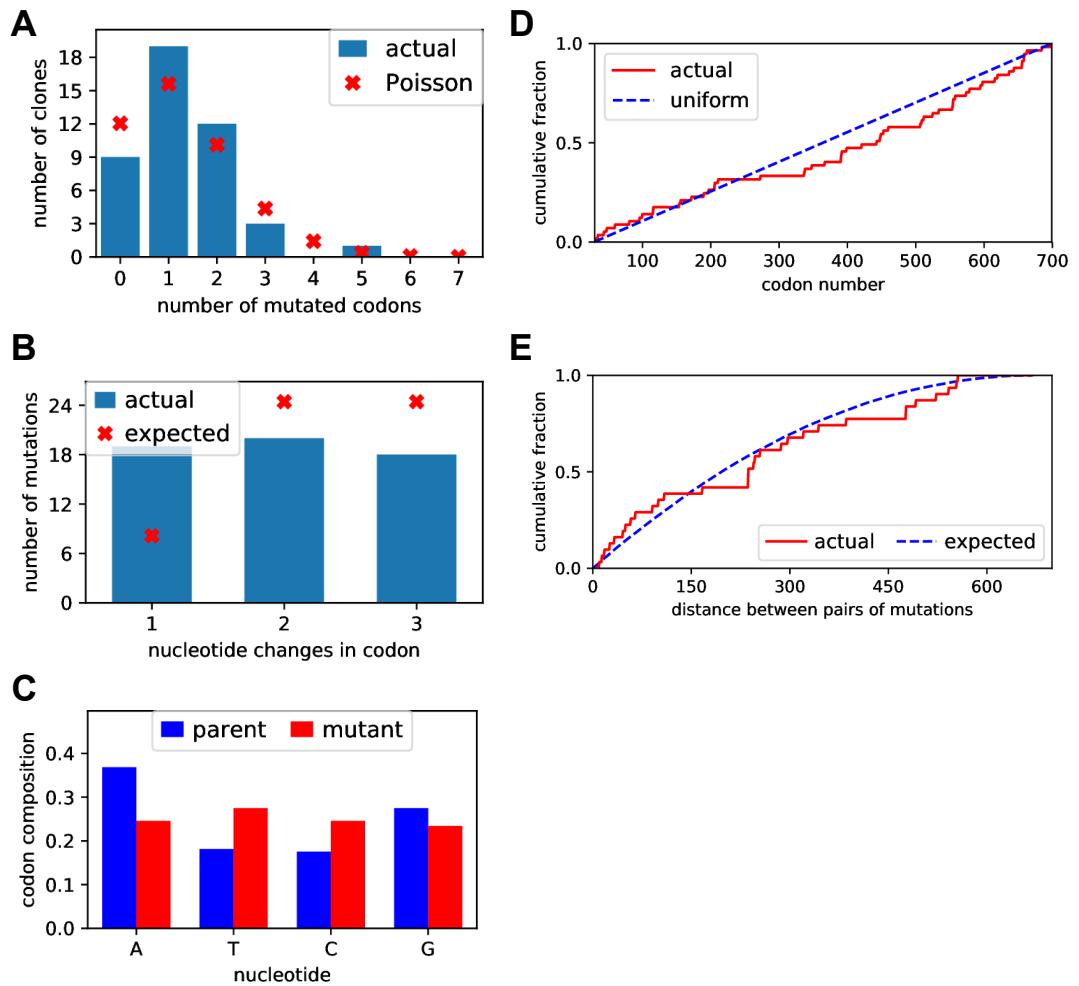

Figure 2-Figure supplement 1. We Sanger sequenced 44 clones of BG505 Env sampled roughly evenly from each of the three replicate mutant plasmid libraries. **(A)** There was an average of 1.5 mutant codons per clone, with the number of mutations per clone roughly following a Poisson distribution. **(B)** The mutant codons had a mix of single-, double-, and triple-nucleotide changes, with an elevated number of single-nucleotide changes than expected. **(C)** Nucleotide frequencies were fairly uniform in the mutant codons. **(D)** Mutations were distributed roughly evenly along the mutagenized region of *env* (30-699 in the sequential numbering scheme used in this plot). **(E)** For clones with multiple mutations, we computed the pairwise distance in primary sequence between each codon mutation and plotted the cumulative distribution of these distances (red line). We also simulated the expected distribution of pairwise distances if mutations occurred entirely independently (blue line). The observed distribution is close to the expected distribution. Comparable data for the BF520 libraries is provided in ?.

Figure 3-Figure supplement 1. This table gives the average frequencies of nonsynonymous, synonymous, and stop-codon mutations as plotted in **Figure 3**. Note that there is only one *DNA* sample for BF520, so that same sample is repeated three times in the sample in conjunction with each BF520 replicate. We calculate the error-corrected *pre*-selection mutation frequency as the *mutDNA* frequency minus the *DNA* frequency, and the error-corrected *post*-selection mutation frequency as the *mutvirus* frequency minus the *virus* frequency. We then use these error-corrected frequencies to calculate the *percent* of mutations remaining after selection for each replicate and type of mutation.

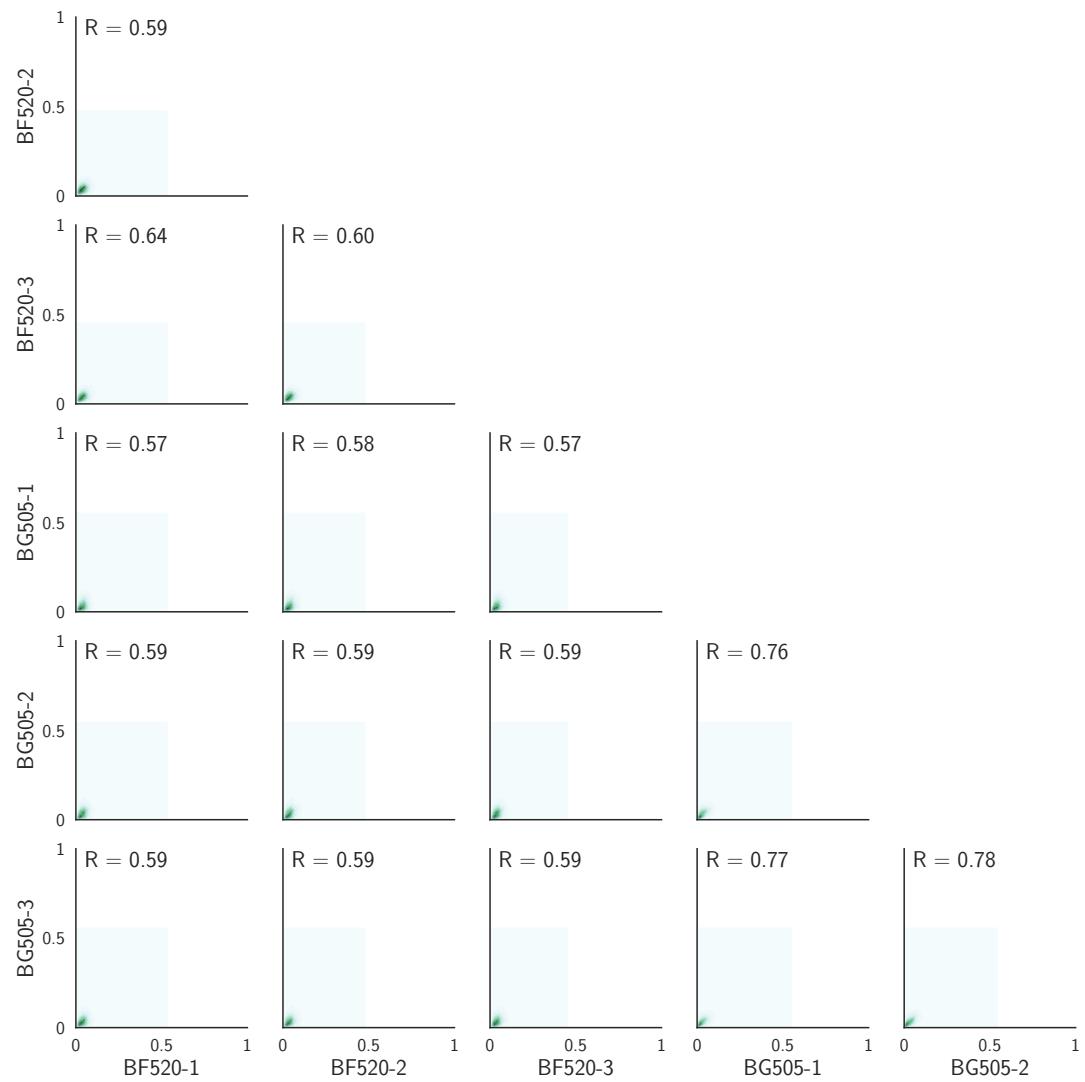

Figure 3-Figure supplement 2. This figure shows the same data as in **Figure 3B** except that it shows KDE contour plots rather than points. As is obvious from this representation, the vast majority of the points fall near the origin (very low preference in both replicates), and most of the correlation signal is therefore due to the relatively modest number of amino acids that have high preference at any given site. This is expected, since most amino acid mutations at most sites will be strongly deleterious, and so have low preference.

substituted significant_shift	False	True
False	545	84
True	22	8

Figure 7-Figure supplement 1. The sites of significant shifts as determined in **Figure 6B** are somewhat more likely to be among the sites that have substituted between BG505 and BF520. However, this association is only borderline statistically significant, with $P = 0.055$ using a Fisher's exact test.

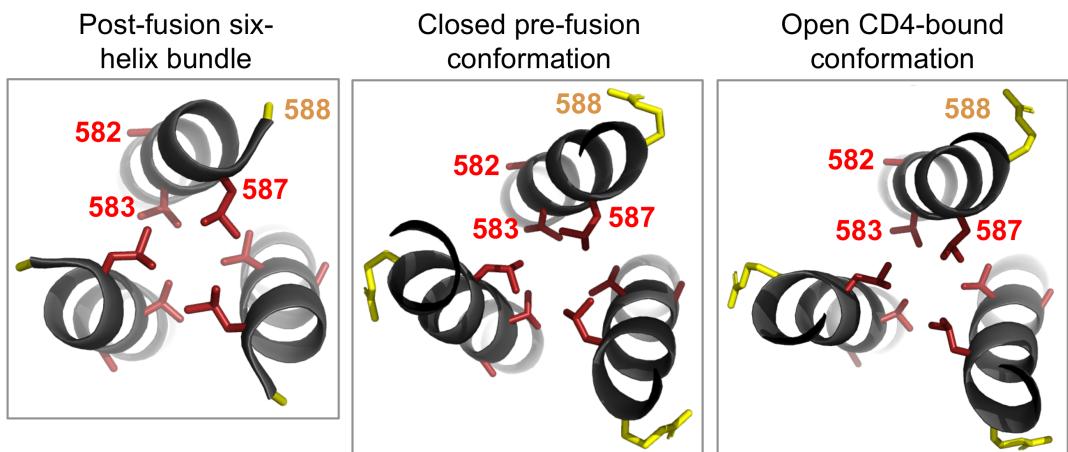

Figure 7-Figure supplement 2. The left-most panel shows the six-helix bundle of Env (PDB 1ENV; ?), focusing on the central three helices, each of which is derived from a different Env monomer and which pack together to form the bundle's core. The other three helices that make up this bundle are located in another part of the structure. There are ~80 residues per monomer that are resolved in this structure, including four significantly shifted sites and five substituted sites. Of these, three of the shifted sites (582, 583, and 587) and one substituted site (588) form a cluster at one end of the bundle. We show the side chains for each of these sites colored according to whether the site has shifted (red) or substituted (yellow). We wondered whether this cluster was unique to the six-helix bundle, but found that it is also present in roughly the same structural arrangement in both the closed pre-fusion conformation (center panel) and the open CD4-bound conformation (right panel; note that some of the surrounding residues in both the closed and open structures have been hidden for the sake of clarity). As shown in **Figure 6C**, each of the shifted sites are more tolerant of mutations in BG505 than in BF520, indicating they are of greater structural and functional importance in BF520. The two shifted sites that point inward towards the bundle's core (583 and 587) may be important for packing. Based on these structures, it is difficult to discern if or how the substituted site may impact the preferences at the shifted sites nearby.

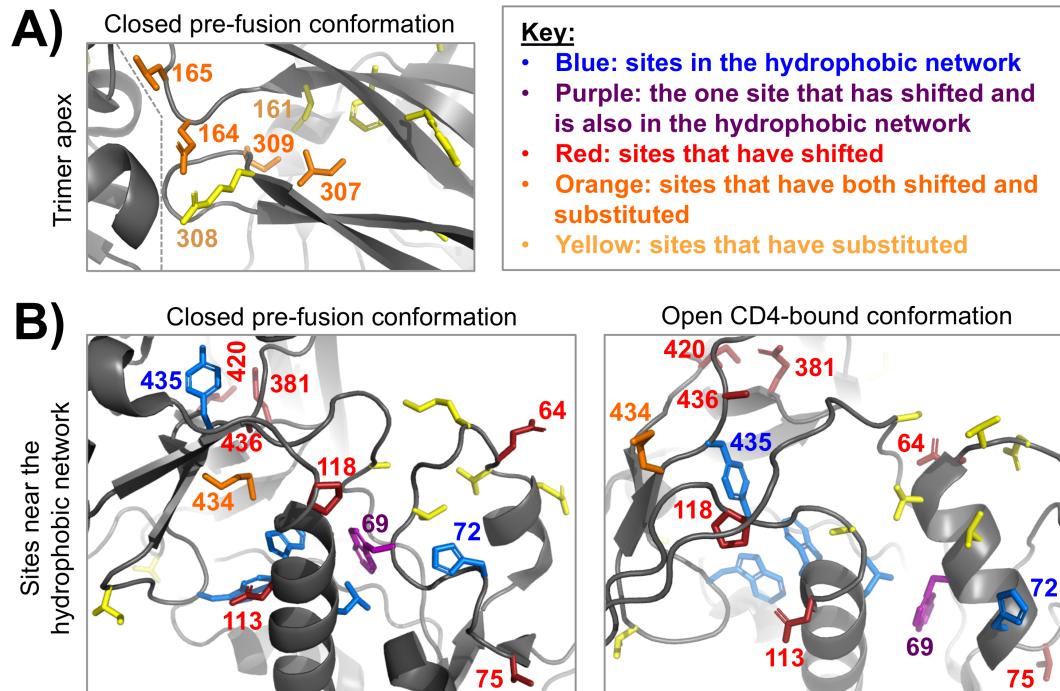

Figure 7-Figure supplement 3. This figure gives a fine-grained view of two clusters of shifted sites, both of which reside in highly dynamic regions of Env. In each structure, we only show side chains for shifted sites or other sites of interest, which include substituted sites and sites that are proposed to take part in a hydrophobic network that helps control Env's dynamics ?. These side chains are colored differently according to the key. **(A)** This panel shows a cluster of four shifted sites at the apex of the closed pre-fusion conformation of Env (PDB 5FYL; ?), a region that is not resolved in the open CD4-bound conformation. These sites are in Env's first/second variable loop (164 and 165) and its third variable loop (307 and 309), which pack against one another and against an adjacent Env protomer (the inter-protomer boundary is indicated by a dashed line). Each of the shifted sites has substituted. And these sites are in the immediate vicinity of other non-shifted, but substituted sites. Thus, it seems likely that these shifts at least partially arise from short-range epistatic interactions within this cluster. However, longer-range epistatic interactions with more distant sites also seem plausible given the highly dynamic nature of this region. **(B)** This panel shows a cluster of shifted sites that are adjacent to a network of hydrophobic residues (blue/purple) that help mediate the conformational change between the closed pre-fusion state to the open CD4-bound state ?. One of the shifted sites (purple) is in this network. These sites are shown in context of both structural states, the latter of which is from (PDB 5VN3; ?). Nearly one third of the shifted residues cluster within this structural region (9/30). In contrast to panel (A), only a few of the shifted sites are adjacent to substitutions or have substituted themselves. This trend is found in both the closed and open conformations, suggesting that the shifts may be primarily due to long-range epistatic interactions.

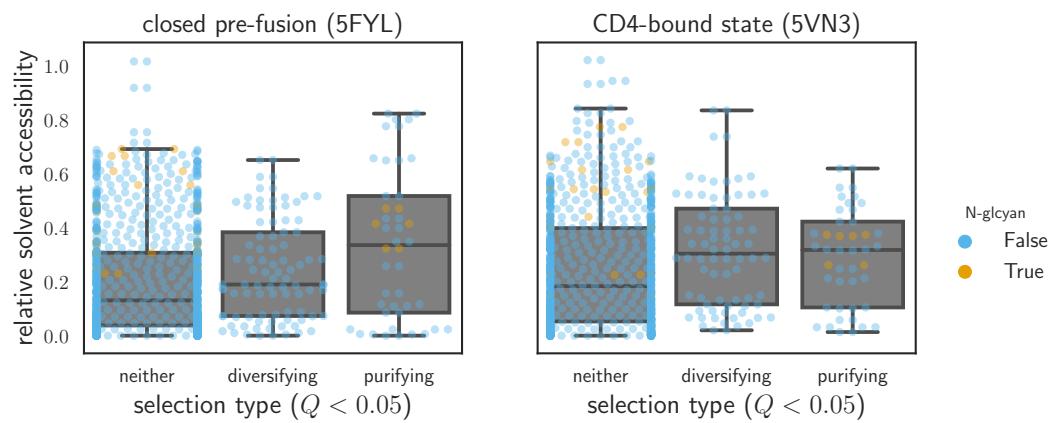

Figure 9—Figure supplement 1. Sites are grouped by whether they have $\omega_r > 1$ (diversifying selection) or $\omega_r < 1$ (purifying selection) at $Q < 0.05$ in *both* Envs, or whether they fall into neither of these categories. Relative solvent accessibilities were calculated as in **Figure 7**. As can be seen from these box plots with overlaid points for each site, sites of both diversifying and purifying selection tend to have higher relative solvent accessibility than other sites.

Figure 9—Figure supplement 2. This plot shows all sites that are N-linked glycosylation motifs in both BG505 and BF520. Each motif is named by the residue number of the asparagine, and the preferences (averaged across replicates) for each Env are shown as well as the frequencies of amino acids across the clade A alignment at each of the three positions in the motif (N-X-S/T). As can be seen from this plot, the experiments measure relatively broad mutational tolerance at many sites where the natural Env sequences have a strongly conserved motif. We suspect this is because many glycans serve as a shield against immunity in nature – a function that is not required in cell culture.

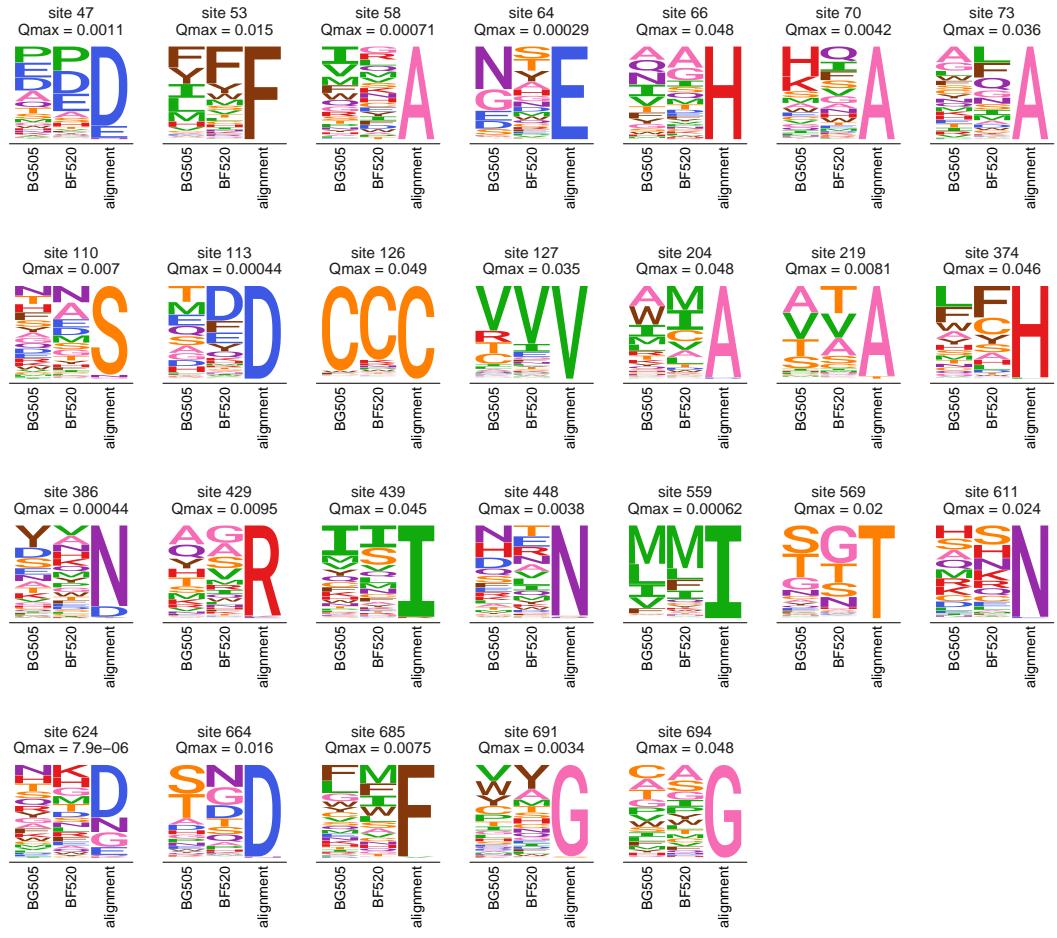

Figure 9–Figure supplement 3. This plot shows all sites that are evolving more slowly than expected in natural sequences given the preferences measured in both Envs. Specifically, it shows all sites with $\omega_r < 1$ at $Q < 0.05$ for the ExpCMs for *both* BG505 and BF520. For each site, the plots show the preferences averaged across replicates and re-scaled for each Env, as well as the frequencies of amino acids in the clade A Env alignment. The Q -value indicated is the maximum of that for the two Envs.
